Difference-in-differences recap

Difference-in-differences (DD) typically relies on panel data, with repeat observations of two or more groups (i) over time (t).

$$y_{it} = \beta_0 + \beta_1 treat_i + \beta_2 post_t + \beta_3 (treat_i \times post_t) + \gamma X_{it} + u_{it}$$

The key assumption is one of common trends: conditional on X, the change in Y over time for untreated units represents what would have happened to treated units, in the absence of treatment.

Difference-in-differences recap

What OVB problem(s) does DD solve? (1) treated observations may differ systematically from untreated observations (β_1), and (2) treated observations may have experienced secular change over time in the absence of treatment (β_2).

OVB remains if there are omitted variables correlated with $treat \times post$ and the outcome y. For example: unobserved factors that change differentially for treated observations (implying non-parallel trends).

LPO 8852 (Corcoran)

Lecture 6

Last update: October 19, 2021 3 / 47

Difference-in-differences recap

DD was our first attempt to address selection on *unobservables*. Treatment need not be randomly assigned, and treated and untreated units *can* differ systematically prior to treatment (this is captured by β_1 , or the group specific coefficients in the generalized DD).

As long as these unobserved differences do not change over time, DD can eliminate the unobserved selection bias

Panel data

Panel, longitudinal, or cross-sectional time series data consist of observations on cross-sectional units (e.g., students, schools, hospitals, neighborhoods, counties, states) at multiple points in time.

- N cross-sectional (panel) units and T time periods ($T \ge 2$)
- A balanced panel has exactly N × T observations (T time observations for all N panel units)
- ullet An unbalanced panel has T_i observations for panel unit i, where T_i is not the same for all i

Differs from a pooled cross-section, although panel methods can be used with this type of data (e.g., Kearney & Levine (2019) example)

Panel data - reshape

Moving between *long* and *wide* format in Stata with reshape, beginning with *wide* data

- i() contains the time invariant variables (e.g., ID, gender)
- j() specifies the time variable to be created (e.g., year)
- The list of time varying variables are "stubs" that end in the j suffix

reshape long stubnames, i(varlist) j(varname)

- If j() consists of string rather than numeric values, use the string option
- Example time-varying variable names: score98, score99, score00 (Stata may have problems with 00 as a j() value if string is not used).

Panel data - reshape

Moving between *long* and *wide* format in Stata with reshape, beginning with *long* data

- i() contains the time invariant variables (e.g., ID, gender)
- j() specifies the time variable (e.g., year)
- The list of time varying variables are "stubs" that will end in the j suffix, once converted to wide

reshape wide stubnames, i(varlist) j(varname)

- After reshaping, Stata allows you to revert back easily without losing information. E.g., after the above command just type reshape long
- Most panel regression commands expect the data to be in long format.

Lecture 6

Last update: October 19, 2021 9 / 47

Panel data - advantages

Why use panel data?

- Can help us answer questions not possible with a cross-section or time-series approach
- Can generate measures not possible with cross-sectional or time series data (e.g., growth, work spells)
 - ► If 50% of women are working in year t, does this reflect 50% of women working at any given point, or 50% of women who work all the time?
- Allows us to address unobserved heterogeneity that is fixed over time ("fixed effects")

Selection bias revisited

Interpretation of regression coefficients as causal is often complicated by selection bias. Example:

$$y_i = \beta_0 + \beta_1 x_i + u_i$$

with $E(u_i|x_i) \neq 0$ because we believe potential outcomes are not independent of x. We have attempted to mitigate selection bias through the inclusion of additional covariates or via matching, but this only solves the problem if conditioning on these observables (or the propensity score) eliminates OVB.

In practice we are often more concerned about selection on unobservables.

LPO 8852 (Corcoran)

Lecture (

Last update: October 19, 2021 11 / 47

Unobserved heterogeneity

Suppose there are unobserved, fixed differences across units (c_i) that affect the outcome and are (potentially) correlated with the explanatory variable of interest:

$$y_i = \beta_0 + \beta_1 x_i + c_i + u_i$$

 c_i could represent the effects of ability, health, motivation, intelligence, parental resources, managerial quality, organizational culture, state/local policies or regulations, etc.

Within transformation

Now suppose that panel data are available with multiple observations per i:

$$y_{it} = \beta_0 + \beta_1 x_{it} + c_i + u_{it}$$
 $t = 1, ..., T$ $\forall i$

Now within each panel unit i, take the average over t on both sides and subtract the average from each it observation:

$$\bar{\mathbf{v}}_i = \beta_0 + \beta_1 \bar{\mathbf{x}}_i + \mathbf{c}_i + \bar{\mathbf{u}}_i$$

$$y_{it} - \bar{y}_i = \beta_1(x_{it} - \bar{x}_i) + (u_{it} - \bar{u}_i)$$

This is called "de-meaning" or the "within" transformation (sometimes denoted $\tilde{y_i}$). Notice that the intercept β_0 and the c_i "difference out." c_i differences out only if it is *time invariant*.

LPO 8852 (Corcoran)

Lecture (

Last undate: October 19, 2021, 13 / 47

Within transformation

Under certain assumptions, an OLS regression of the de-meaned y on the de-meaned x will yield unbiased and consistent estimates of β_1 .

$$v_{it} - \bar{v}_i = \beta_1(x_{it} - \bar{x}_i) + (u_{it} - \bar{u}_i)$$

This is the fixed effects or "within" regression, and extends to more than one explanatory variable $(x_1, ..., x_k)$.

Explanatory variables x_j that are time *invariant* fall out of the model. (They all equal their within-group mean, so the within-transformation equals zero). Examples: gender, race or ethnicity, ...

LPO 8852 (Corcoran)

Lecture

Stata panel commands

Stata has many useful commands for working with panel data. Typically these require that you first declare the data to be a panel using xtset:

- xtset panelvar timevar
- The panelvar must be numeric. If it is not, you can use encode: encode panelvar, gen(panelvar2)
- It is possible to tell Stata in the xtset options what units of time the data represent—e.g., years, quarters, minutes (useful for some purposes)
- xtset alone will report back the panel settings

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 15 / 47

Stata panel commands

Other useful Stata panel data commands for description:

- xtdescribe—to see patterns of participation
- xtsum—for descriptive statistics that show between- and within-unit variation
- xttab—for one-way tabulations with separate counts within and between units
- xttrans—for transition probabilities (movement between categories of a categorical variable)
- xtline and xtline, overlay—for separate line graphs by panel unit (see in-class exercise)

LPO 8852 (Corcoran)

Lecture

Last undate: October 19, 2021, 16 / 47

Stata panel commands

The fixed effects ("within") regression model can be implemented in Stata using xtreg or areg (more on this shortly).

Related models:

- First-difference model—also eliminates c_i but uses one fewer observation per cross-sectional unit
- Long-difference model—where differenced observations are further apart in time

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 17 / 47

First difference model

Suppose we have two time periods (T=2) for each cross-sectional unit i, and assume the linear model below applies in both periods:

$$y_{i2} = \beta_0 + \beta_1 x_{i2} + c_i + u_{i2}$$
$$v_{i1} = \beta_0 + \beta_1 x_{i1} + c_i + u_{i1}$$

Now subtract period 1 from period 2 for the "first difference":

$$\Delta y_i = \beta_1 \Delta x_i + \Delta u_i$$
$$y_i^* = \beta_1 x_i^* + u_i^*$$

Because c_i is time-invariant, it differences out of the model. Notice the constant β_0 also differences out.

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 18 / 47

First difference model

The first difference model can be estimated using OLS, as long as the usual OLS assumptions apply to it:

- The new error term $u_i^* = \Delta u_i$ is uncorrelated with the new explanatory variable, $x_i^* = \Delta x_i$.
- This requires that we have no cross-period correlations between u and x: called strict exogeneity
- The x_i must vary over time for at least some i, else they difference out (same as the within transformation)

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 19 / 47

First difference model

Example using panel of Texas elementary schools:

- use Texas elementary panel 2004 2007.dta
- xtset campus year
- xtdescribe
- egen avgclass = rowmean(cpctg01a-cpctgmea)
- rename ca311tar avgpassing
- reg avgpassing avgclass if year == 2007 (cross-sectional regression for 2007)

Note: avgclass is the mean class size across grades, and avgpassing is the school average passing rate across grades and subjects.

First difference model

Having declared the dataset as a panel, Stata recognizes the d. prefix as a "difference operator":

- reg d.avgpassing d.avgclass if year == 2007, noconstant
- This is the first difference regression
- d. can be used after xtset or tsset (time series set)
- Note suppression of the constant. In theory the constant term differences out. In practice can still estimate with a constant, which allows for a year-to-year time trend.

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 21 / 47

First difference model

A few things to note in the example:

- Change in coefficient on class size: does it make sense?
- Change in sample size (re: unbalanced panel due to missing values)

A few things to think about:

- Is strict exogeneity likely to hold in this circumstance?
- Where is the identifying variation coming from?
- How much variation is there in the *change* in passing rates (Δy) and class size (Δx) ?
- Do outliers dominate the variation in changes?

gen diffavgpassing = d.avgpassing
/* create variable containing FD */

First difference model

The first difference model is easily generalizable to multiple years (T > 2).

- Each year of data is differenced with the prior year
- 1st period is sacrificed
- Must continue to think about OLS assumptions, e.g. strict exogeneity

reg d.avgpassing d.avgclass, noconstant
table year if e(sample)

* note 1st year of data is not used

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 23 / 47

Fixed effects model

In the *(one-way) fixed effects* model, we treat the c_i as parameters to be estimated:

$$y_{it} = \beta_0 + \beta_1 x_{it} + c_i + u_{it}$$

Effectively we are allowing for a *unique intercept* for every cross-sectional unit i. This is feasible to estimate since each i is observed multiple times.

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 24 / 47

LSDV approach

Now we are estimating the intercept β_0 , slope β_1 , and (N-1) intercepts, the "fixed effects"

This can be done thorough brute force by including (N-1) dummy variables in the regression, sometimes called the "least squares dummy variable" (LSDV) model:

- reg avgpassing avgclass i.campus
- For this example limit to year>=2006 and houston==1 so that the number of schools is manageable.
- areg is equivalent but suppresses the dummy coefficients from the output
- areg avgpassing avgclass, absorb(campus)

LPO 8852 (Corcoran)

Lecture (

Last update: October 19, 2021 25 / 47

LSDV approach

There are a number of reasons why you might not want to do it this way:

- Could be time-consuming and harder on memory with large datasets (re: you are creating dummy variables for each unique i)
- Soaks up degrees of freedom; may result in the number of regressors exceeding the number of observations
- Often we are not interested in the estimates of the fixed effects themselves, so there is no need to see/report them.
- Exception: recent "school effects" and "teacher effects" studies work explicitly with fixed effects estimates (ĉ_i)

LSDV provides equivalent estimates to a model in which the original data is transformed using the "fixed effects" or "within" transformation shown earlier:

$$y_{it} = \beta_0 + \beta_1 x_{it} + c_i + u_{it}$$
 $t = 1, ..., T$ $\forall i$

For each unit i, take the average over t on both sides and subtract:

$$\mathbf{v}_{it} - \bar{\mathbf{v}}_i = \beta_1(\mathbf{x}_{it} - \bar{\mathbf{x}}_i) + (\mathbf{u}_{it} - \bar{\mathbf{u}}_i)$$

The c_i "difference out."

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 27 / 47

Fixed effects model

The transformed model can be estimated using OLS

- xtreg avqpassing avqclass, fe
- Note xtset must have been declared
- While the fixed effects are not estimated directly, can "back out" a prediction: $\hat{c}_i = \bar{v}_i \bar{x}_i \hat{\beta}_1$
- predict schlfe, u

Compare xtreg, areg and first difference when T=2

- xtreg augpassing augclass3, fe
- areg avgpassing avgclass3, absorb(campus)
- reg d.avgpassing d.avgclass3, noconstant

LPO 8852 (Corcoran)

Lecture (

Last update: October 19, 2021 29 / 47

Fixed effects model

A few notes about xtreg, fe

- ullet FE is more efficient (smaller standard errors) than first differencing if the error terms are serially uncorrelated and T>2
- Assumes no correlation in u across units of panel i (some tests for this using user-written xtscd, xttest3)
- The estimates of the fixed effects themselves (c_i) are unbiased but inconsistent in large samples. (Why? As the number of panel units grows (N → ∞) the number of parameters to estimate grows).
- xtreg has not historically allowed svy specification (for complex sampling designs) but can use pweights and cluster() option. See also the mixed (or xtmixed) command for an alternative.

Stata actually fits the following model with xtreg:

$$(v_{it} - \bar{v}_i + \bar{v}) = \beta_0 + \beta_1(x_{it} - \bar{x}_i + \bar{x}) + (u_{it} - \bar{u}_i + \bar{u})$$

Where the values with a bar but no subscript are the grand means. This includes an intercept which is the average of the fixed effects (c_i) .

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 31 / 47

Fixed effects model

Fixed effects considerations:

- Where is the identification coming from?
- How much variation is there within panel units? When small, one risks imprecise estimates
- For stats on within- and between- school variation can use xtsum:

xtsum avgpassing avgclass

Decomposition of variation in xtsum:

$$s_w^2 = \frac{1}{NT - 1} \sum_{i} \sum_{t} (x_{it} - \bar{x}_i)^2$$
$$s_b^2 = \frac{1}{N - 1} \sum_{i} (\bar{x}_i - \bar{x})^2$$

$$s_o^2 = \frac{1}{NT - 1} \sum_i \sum_t (x_{it} - \bar{x})^2$$

Note \bar{x} is the grand mean of x. Can also write:

$$s_w^2 = \frac{1}{NT - 1} \sum_i \sum_t (x_{it} - \bar{x}_i + \bar{x})^2$$

because adding a constant (\bar{x}) will not affect s_w^2

LPO 8852 (Corcoran)

Lecture 6

Last update: October 19, 2021 33 / 47

xtsum

xtsum also shows the min and max of:

- x_{it}: overall
- \bar{x}_i : between
- $(x_{it} \bar{x}_i + \bar{x})$: within

Note: on xtsum, see also https://www.stata.com/support/faqs/statistics/decomposed-variances-in-xtsum/

Other useful output from xtreg:

		(within) regr : campus	ession		Number of Number of	obs = groups =	350 180

Lecture

Last update: October 19, 2021 35 / 47

Fixed effects model

Other useful output from xtreg:

- F-test for joint significance of fixed effects (null hypothesis H₀ is that all fixed effects are zero). If rejected, fixed effects model is a reasonable assumption and regular OLS would provide inconsistent estimates. In practice, rarely rejected.
- R² within: variance "explained" by within-group deviations from mean
- R^2 between: variance in group means \bar{y}_i "explained" by the group mean x's: \bar{x}_i
- sigma_u estimate of the standard deviation in fixed effects (c_i)

Fixed effects model: assumptions

- **FE.1:** linear model $y_{it} = \beta_1 x_{it1} + ... + \beta_k x_{itk} + c_i + u_{it}$
- FE.2: cross-sectional units are a random sample
- FE.3: xit varies over time for some i, no perfect collinearity
- FE.4: ∀t, E(u_{it}|X_i, c_i) = 0 or the expected value of u given x in all time periods is zero (strict exogeneity)
- **FE.5**: $Var(u_{it}|X_i, c_i) = Var(u_{it}) = \sigma_u^2$ homoskedasticity
- **FE.6:** for $t \neq s$ errors are uncorrelated: $Cov(u_{it}, u_{is}|x_i, c_i) = 0$. No serial correlation.

Under FE.1-FE.4, fixed effects model (and first difference model) is unbiased. Adding FE.5-FE.6, fixed effects model is BLUE. If FE.6 holds, fixed effects is more efficient than the first difference model. Can relax homoskedasticity assumption and calculate robust standard errors.

LPO 8852 (Corcoran)

Lecture 6

Last update: October 19, 2021 37 / 47

Fixed effects model: assumptions

Note: the econometric theory described here is for "short" panels, with N large relative to T. If the opposite is true in your context, use FE model with caution (see Wooldridge chapter 14, Cameron & Trivedi).

Two-way fixed effects model

The "two-way" fixed effects model includes fixed effects for time periods. There is no explicit command for two-way models, rather can just include time dummies

```
xtreg avgpassing avgclass i.year, fe
* the i.year syntax introduces (T-1) time effects
test _Iyear_2006 _Iyear_2007
* joint test that time effects = 0
```

As with one-way fixed effects model, requires variation across units within time periods $\it t$.

LPO 8852 (Corcoran)

Lecture 6

Last update: October 19, 2021 39 / 47

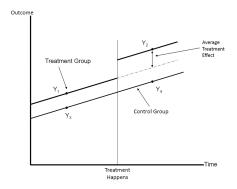

Two-way fixed effects model

The DD model—two-group two-period and generalized—is effectively a two-way fixed effects model:

$$y_{it} = \beta_0 + \beta_1 treat_i + \beta_2 post_t + \beta_3 (treat_i \times post_t) + \gamma X_{it} + u_{it}$$

There are group "fixed effects" which represent separate intercepts for the treated and untreated units, and "time effects" which capture variation over time within group. The time effect is allowed to vary for the treated and untreated groups.

Two-way fixed effects model

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 41 / 47

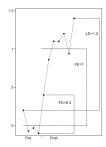

Comparison of models

It is important to be attentive to where the variation in FE models is coming from:

- Fixed effects ("within") model: uses deviations from unit means, e.g., mean "pre" vs. mean "post"
- First differences model: uses variation in successive time periods, e.g., just prior to and just after a "treatment" (a change in x)
- Long differences model: compares outcomes well before and well after a "treatment"

To evaluate these in your situation, need some idea of the speed in which \boldsymbol{x} affects \boldsymbol{y}

Comparison of models

Source: Nichols (2007). Figure shows one panel (i)'s contribution to the estimated effect of a treatment that = 1 in post period (t > 4)

LDO 9952 (Corcoran)

Lecture

Last update: October 19, 2021 43 / 47

Fixed effects models in other applications

Fixed effects models are not exclusively used with panel data in which cross-sectional units i are observed in multiple time periods. They are also used with grouped or clustered data. For example:

- Family fixed effects, where the family is the cross-sectional unit and siblings are the group members (akin to the time dimension)
- School fixed effects with student-level data, where each school has its own intercept

Comparison of models

The researcher needs to provide a convincing rationale for why the unobserved variable should be considered fixed over time

- Why did a mother's employment status change between siblings?
- Why did only 1 of 2 siblings participate in Head Start?
- Why did a student switch from a traditional school to a charter school?
- Why did an elementary school receive a new principal?

LPO 8852 (Corcoran)

Lecture

Last update: October 19, 2021 45 / 47

Standard errors

The assumption that errors u_{it} are i.i.d. is not often satisfied in panels. With repeat observations on the same cross-sectional unit, it is likely that errors are correlated across observations for the same i.

- If y is over-predicted in one period for a given i, it is likely to be over-predicted in the next period.
- For "short" panels (large N, small T), can use cluster-robust standard errors
- The "cluster" is typically the cross-sectional unit, although when the regressor of interest is aggregated at a higher level (e.g., state), can cluster at that level. Theory requires large N and that higher levels nest the cross-sectional units.
- vce(robust) or robust in xtreg assumes data are clustered
- Cluster-robust standard errors from areg are different from those using xtreg, fe. It is recommended that you use xtreg.

LPO 8852 (Corcoran)
